## Abstract

  The *teosinte branched1* (*tb1*) gene, a repressor of lateral organ growth, is a major QTL involved in branching differences between maize and its wild progenitor, teosinte. Further studies have shown that the insertion of a transposable element (Hopscotch) upstream of *tb1* enhances its expression, causing the reduction in branching observed in domesticated maize. Observations of the maize *tb1* allele in teosinte individuals, coupled with estimates of the age of insertion of the Hopscotch element, led us to investigate the role of *tb1* in teosinte. Results from genotyping across many natural populations suggest that the Hopscotch element is segregating at a higher than expected frequency in a number of populations of both subspecies *parviglumis* and subspecies *mexicana*.   Analysis of linkage disequilibrium between the Hopscotch element and variation in surrounding regions does not support a hypothesis of recent introgression from maize into teosinte, and we find no evidence of environmental correlations that might suggest recent selection. Finally, two greenhouse experiments fail to find an important role for *tb1* in controlling tillering in natural populations of *parviglumis*. Our findings suggest that the role of the Hopscotch in tillering in teosinte is not as straightforward as is in domesticated maize, and that other loci may play a role in observed variation in tillering in teosinte.

*Check citation format for AJB. I don't think it's numbers. adjust bibliography style accordingly*

# Introduction

Domesticated crops and their wild progenitors provide an excellent system in which to study adaptation and genomic changes associated with human-mediated selection (42). Perhaps the central focus of the study of domestication has been the identification of genetic variation underlying agronomically important traits such as fruit size and plant architecture (38). Additionally, many domesticates show reduced genetic diversity when compared to their wild progenitors, and an understanding of the distribution of diversity in the wild and its phenotypic effects has become increasingly useful to crop improvement (32). But while some effort has been invested into understanding how wild alleles behave in their domesticated relatives *CITE* , very little is known about the role that alleles found most commonly in domesticates play in natural populations of their wild progenitors. *CITE; perhaps Arias and Rieseberg 1994 TAG?*

Maize (*Zea mays* ssp. *mays*) was domesticated from the teosinte *Zea mays* ssp. *parviglumis* (hereafter, *parviglumis*) roughly 10,000 B.P. in southwest Mexico (39; 36). *shouldn't this be 9K BP? what does Piperno 2009 say?* Domesticated maize and the teosintes are an attractive system in which to study domestication due to the abundance of genetic tools developed for maize and well-characterized domestication loci (27; 10; 29). Additionally, large naturally occurring populations of both *Zea mays* ssp. *parviglumis* (the wild progenitor of maize) and *Zea mays* ssp. *mexicana* (highland teosinte; hereafter *mexicana*) can be found throughout Mexico (54; 28), and genetic diversity and effective population size ( $N_e$ ) of these taxa is estimated to be high (43) relative to other plants (37). *what are nybom's estimates? i didn't think mine were that high and don't remember Nybom giving  $N_e$  estimates*

Many morphological changes are associated with the domestication of maize, and understanding the genetic basis of these changes has been a focus of maize research

for a number of years(10). One of the most dramatic changes is found in plant architecture: domesticated maize is characterized by a central stalk with few tillers and lateral branches terminating in a female inflorescence, while teosinte is highly tillered and bears tassels (male inflorescences) at the end of its lateral branches. The *teosinte branched1* (*tb1*) gene, a repressor of organ growth, was identified as a major QTL involved in branching differences between maize and teosinte (14; 11; 34). *an odd assortment of cites. why not the 1997 nature paper?* Further work showed that the insertion of a 4.9 kb retrotransposon (Hopscotch) in the upstream control region of *tb1* led to increased expression of this gene, causing the reduction in branching observed in domesticated maize (46). The effects of this insertion have been observed in tiller number in maize, but little is known about its role, if any, in teosinte (46). Dating of this element has suggested that its insertion predates the domestication of maize, leading to the hypothesis that it was segregating as standing variation in ancient populations of teosinte and increased to high frequency in maize due to selection during domestication (46). Furthermore, (45) investigated the phenotypic effects of 9 teosinte *tb1* alleles in an isogenic maize background and found that the introgressions sort into three distinct phenotypic classes, suggesting that variation at the *tb1* locus may play a functional role in teosinte. *MBH todo*

Tillering, or more specifically lack of tillers in teosinte, may provide an ecological advantage to plants. In species such as teosinte, where plants grow densely packed together, if plants invest more resources into growing taller and fewer resources into tillering, plants may be able to out-compete neighbors for limiting resources such as light. *there must be some citations in ecology lit to support this?* In natural populations of teosinte, variation at the (*tb1*) locus may then play a role in the ecology of teosinte. In this study we aim to characterize the distribution of the Hopscotch insertion in *parviglumis*, *mexicana*, and landrace maize, and to examine the phenotypic effects

of the insertion in *parviglumis*. We use a combination of PCR genotyping for the Hopscotch element in our full panel and sequencing of two small regions upstream of *tb1* in a subset of teosinte populations to explore patterns of genetic variation at this locus. Finally, we test for an association between the Hopscotch element and tillering phenotypes in a population of *parviglumis*.

## Methods

### Sampling and Genotyping

We sampled 1,110 individuals from 350 accessions (247 maize landraces, 17 *Zea mays* ssp. *mexicana* populations, and 86 *parviglumis* populations) and assessed the presence or absence of the Hopscotch insertion (??, ??). DNA was extracted from leaf tissue using a modified CTAB approach (15; 35). We designed primers using PRIMER3 (44) implemented in Geneious (30) to amplify the entire Hopscotch element, as well as an internal primer allowing us to simultaneously check for possible PCR bias between presence ( 5 kb amplification product) and absence ( 300 bp amplification product) of the Hopscotch insertion. Two PCRs were performed for each individual, one with primers flanking the Hopscotch (HopF/HopR) and one with a flanking primer and an internal primer (HopF/HopIntR). Primer sequences are HopF, 5'-TCGTTGATGCTTTGATGGATGG-3'; Hop R, 5'-AACAGTATGATTTTCATGGGACCG-3'; and HopIntR, 5'-CCTCCACCTCTCATGAGATCC-3' (1). Homozygotes show a single band for either the Hopscotch element ( 5 kb) or the absence of the element ( 300 bp), while heterozygotes are three-banded, showing a band for both the presence and absence of the Hopscotch element as well as a band for the internal primer set (2). *fig references still need to say "Fig" etc., all the ref function does is set the number automaticall* .

When only one PCR resolved well, we scored one allele for the individual, which explains the odd number of alleles included in our analyses. We used Phusion High Fidelity Enzyme (Finnzymes, Inc.) and the following conditions for amplifications: 98° for 3 min, 30 cycles of 98° for 15 s, 65° for 30 s, and 72°C for 3 min 30 s, with a final extension of 72° for 10 min. PCR products were visualized on a 1% agarose gel and scored for presence/absence of the Hopscotch based on band size.

## Sequencing

In addition to genotyping, we chose a subset of *parviglumis* individuals for sequencing. We chose twelve individuals from each of four populations from Jalisco state, Mexico (San Lorenzo, La Mesa, Ejutla A, and Ejutla B). For amplification and sequencing, we selected two regions approximately 600bp in size from within the 5' UTR of *tb1* (sequenced region 1) and from 1,235 bp upstream of the start of the Hopscotch and 66,169 bp upstream from the start of the *tb1* ORF (sequenced region 2). The 5' UTR (containing sequenced region 1) has been shown to have elevated diversity in *ssp. parviglumis* with respect to maize, while the the area upstream from the Hopscotch (sequenced region 2) has been shown to be critical in determining basal branching and ear architecture (51; 6). *is this true? the area upstream of the hopscotch? those papers just found that something upstream was the causal variant, no?* We designed the following primers using PRIMER3 (44): for the 5' UTR, 5' GGATAATGTGCACCAGGTGT 3' and 5' GCGTGCTAGAGACACYTGTTGCT 3'; for the 50 kb upstream region, 5' TGTCCCTCGCCGCAACTC 3' and 5' TGTACGCCCCGCCCTCATCA 3' (1). We used Taq Polymerase (New England Biolabs) and the following thermal cycler conditions to amplify fragments: 94C for 3 min, 30 cycles of 92C for 40 s, annealing for 1 min, 72C for 40 s, and a final 10 min extension at 72C. Annealing temperatures for

sequenced region 1 and sequenced region 2 were 59.7C and 58.8C, respectively. To clean excess primer and dNTPs we added two units of Exonuclease1 and 2.5 units of Antarctic Phosphatase to 8  of amplification product. This mix was placed on a thermal cycler with the following program: 37C for 30 min, 80C for 15 min, and a final cool-down step to 4C. *redo primers with  all function as above, and degrees above and below as prior*

We cloned cleaned fragments into a TOPO-TA vector (Invitrogen, Carlsbad) using OneShot TOP10 chemically competent *E. coli* cells, with an extended ligation time of 30 min for a complex target fragment. We plated cells on LB agar plates containing kanamycin, and screened colonies using vector primers M13 Forward and M13 Reverse under the following conditions: 96C for 5 min; then 35 cycles at 96C for 30 s, 53C for 30 s, 72C for two min; and a final extension at 72C for 4 min. We visualized amplification products for incorporation of our insert on a 1% agarose TAE gel.

Amplification products with successful incorporation of our insert were cleaned using Exonuclease 1 and Antarctic Phosphatase following the procedures detailed above, and sequenced with vector primers M13 Forward and M13 Reverse using Sanger sequencing at the College of Agriculture and Environmental Sciences (CAES) sequencing center at UC Davis. We aligned and trimmed primer sequences from resulting sequences using the software Geneious (30). Following alignment, we verified singleton SNPs by sequencing an additional one to four colonies from each clone. If the singleton was not present in these additional sequences it was considered an amplification or cloning error, and we replaced the base with the base of the additional sequences. If the singleton appeared in at least one of the additional sequences we considered it a real variant and kept it for further analyses.

## Genotyping Analysis

*please drop scripts for bayenv and STRUCTURE into github*

We examined discrepancies between observed and expected genotype frequencies by calculating Hardy-Weinberg Equilibrium (HWE). To calculate differentiation between populations ( $F_{ST}$ ) and subspecies ( $F_{CT}$ ) we used HierFstat (24). These analyses only included populations in which 8 or more individuals were sampled. To test the hypothesis that the Hopscotch insertion may be adaptive under certain environmental conditions, we looked for significant associations between the Hopscotch frequency and environmental variables using BayEnv (9). BayEnv creates a covariance matrix of relatedness between populations, and then tests a null model that allele frequencies in populations are determined by the covariance matrix of relatedness alone against the alternative model that allele frequencies are determined by a combination of the covariance matrix and an environmental variable, producing a posterior probability (Bayes Factor)(9). We used genotyping and covariance data from Pyhäjärvi et al., (2013) (41) for BayEnv, with the Hopscotch insertion coded as an additional SNP (3). Environmental data were obtained from [www.worldclim.org](http://www.worldclim.org), the Harmonized World Soil Database and [www.harvestchoice.org](http://www.harvestchoice.org), and summarized by principle component analysis Pyhäjärvi et al. (41) (41). *fix tanja cite here*

## Sequence Analysis

For population genetic analyses of sequenced region 1 and sequenced region 2 we used the analysis package of Libsequence (47) to calculate pairwise  $F_{ST}$  between populations, and to calculate standard diversity statistics (number of haplotypes; haplotype diversity; Watterson's estimator  $\theta_W$ ; pairwise nucleotide diversity  $\hat{\theta}_\pi$ ; and Tajima's D). *we should redo these to as shown for hat symbol* To produce a visual representation of differ-

entiation between sequences and to examine patterns in sequence clustering by Hopscotch genotype we used Phylip (<http://evolution.genetics.washington.edu/phylip.html>) *please use the url function for all web addresses* to create neighbor-joining trees with bootstrapping (100 repetitions) to examine the support of nodes in our trees. For creation of trees we also included homologous sequence data from teosinte inbred lines (TILs), some of which are known to be homozygous for the Hopscotch insertion (TIL03, TIL17, TIL09), as well as 59 lines of domesticated maize and landraces (data from Maize HapMapV2, (5)).

*this paragraph below is not sequence data any more. perhaps a different category and heading?* In order to assess patterns of linkage disequilibrium (LD) around the Hopscotch element in the context of chromosomal patterns of LD we used Tassel (3) and calculated LD between SNPs across chromosome 1 using previously published data from twelve plants each of the Ejutla A, Ejutla B, San Lorenzo, and La Mesa populations (41). We chose these populations because we had both genotyping data for the Hopscotch as well as chromosome-wide SNP data for chromosome 1. For each population we filtered the initial set of 5,897 SNPs on chromosome 1 to accept only SNPs with a minor allele frequency of at least 0.1, resulting in 1,671, 3,023, 3,122, and 2,167 SNPs for San Lorenzo, Ejutla B, Ejutla A, and La Mesa, respectively. We then used Tassel (3) to calculate linkage disequilibrium ( $r^2$ ) across chromosome 1 for each population.

We examined evidence of introgression on chromosome 1 in these same four populations (EjuA, EjuB, MSA, SLO) using STRUCTURE (18) and the same phased 55K SNP data from (41) that we used for LD analysis, combined with the corresponding SNP data from a diverse panel of 282 maize lines (8). SNPs were anchored in a modified version of the IBM genetic map ((23), <http://arxiv.org/abs/1307.7313>). We created haplotype blocks using a custom Perl script that grouped SNPs separated by less than 5kb into haplotypes. We ran STRUCTURE at K=2 under the linkage

model, performing 3 replicates with an MCMC burn-in of 10,000 steps and 50,000 steps post burn-in. *i'd like this perl script on github, maybe in this repo or as a gist. also structure input file too. all the stuff we'd need to redo this.*

## Phenotyping of *Zea mays*. ssp. *parviglumis*

To investigate the phenotypic effects of the Hopscotch insertion in teosinte, we conducted an initial phenotyping trial (Phenotyping 1). We germinated 250 seeds of *parviglumis* collected in Jalisco state, Mexico (population San Lorenzo) (26) where the Hopscotch is segregating at highest frequency (0.4375) *accuracy to four digits? this is how many hop and no hop?* in our initial genotyping sample set. In order to maximize the likelihood of finding the Hopscotch in our association population we selected seeds from sites where genotyped individuals were homozygous or heterozygous for the insertion. We chose between 10-13 seeds from each of 23 sampling sites. We treated seeds with fungicide and germinated them in petri dishes with filter paper. Successful germinations (206 individuals) were then planted into one gallon size pots with potting soil and randomly spaced one foot apart on greenhouse benches. Plants were watered three times a day with an automatic drip containing 10-20-10 fertilizer. *i thought they were hand watered?*

Starting on day 15, we measured tillering index, the ratio of the sum of tiller lengths to the height of the plant (4). Tillering index has been shown to be the most effective way to observe the phenotypic effects of the Hopscotch insertion on plant architecture in maize (4). *was it briggs that showed this?* Following initial measurements, we phenotyped plants for tillering index every 5 days through day 40, and then on day 50 and day 60. On day 65 we measured culm diameter between the third and fourth nodes of each plant. Culm diameter is not believed to be correlated

with tillering index, or variation at *tb1* (e.g. Hopscotch genotype). Following phenotyping we extracted DNA from all plants using a modified SDS extraction protocol (<http://www.ars.usda.gov>). We genotyped individuals for the Hopscotch insertion following the protocols listed above. Based on these initial data, we conducted a post hoc power analysis using data from day 40 of phenotyping 1, indicating that a minimum of 71 individuals in each genotype class are needed to detect the observed effect of the Hopscotch on tillering index. *do you still have these posthoc calculations?*

We performed a second phenotyping experiment (phenotyping 2) in which we germinated 372 seeds of *parviglumis*, choosing equally between sites previously determined to have or not have the Hopscotch insertion. Seeds were germinated and planted on day 7 post fruit-case removal into 2 gallon pots. Plants were watered twice daily, alternating between fertilized and non-fertilized water. We began phenotyping successful germinations (302) for tillering index on day 15 post fruit case removal, and phenotyped every five days until day 50. At day 50 we measured culm diameter between the third and fourth nodes. We extracted DNA and genotyped plants following the same guidelines as in phenotyping 1.

Resulting tillering index data for each genotype class did not meet the criteria for a repeated measures ANOVA, *why? what criteria?* so we transformed the data using a Box-Cox transformation ( $\alpha = 0$ ) implemented in the car package in R (20) to improve the normality and homogeneity of variance among genotype classes. We analyzed relationships between genotype and tillering index and tiller number using a repeated measures ANOVA through a general linear model function implemented in SAS v.9.3 (SAS Institute Inc., Cary, NC, USA). Additionally, in order to compare any association between Hopscotch genotype and tillering and associations at other presumably unrelated traits, we performed an ANOVA between culm diameter and genotype using the same general linear model in SAS. *please add SAS scripts/code to a gist or*

something.

## Results

### Genotyping

Genotype of the Hopscotch insertion was confirmed with two PCRs for 837 individuals. Among the 247 maize landrace accessions genotyped, all but 8 were homozygous for the presence of the insertion (??, ??). *please fix table/figure references to say table/figure* Within our *parviglumis* and *mexicana* samples we found the Hopscotch insertion segregating in 37 and 4 populations *this is confusing as the map shows 37 populations. we should be consistent about reporting for all pops, or all pops with  $n \geq 8$ , etc. or at least be explicit what cutoff we are using for each result*, respectively, and at highest frequency in the states of Jalisco, Colima, and Michoacán in central-western Mexico in both subspecies (1) *the map only shows parviglumis. can we add mexicana? the text makes it seem as if both should be on the map*. We examined Hardy-Weinberg equilibrium in a total of 14 populations (10 *parviglumis* and 4 *mexicana*) with more than 8 individuals sampled per population. Three populations (RIMPA0073, RIMPA0093, and RIMPA0158) show evidence of deviations from expected genotype frequencies under the assumptions of HWE ( $p < 0.05$ ). *in what direction? too many hets? what's the  $F$ ?*

*please fix whitespace and black border on figure*

Using our Hopscotch genotyping data, we calculated differentiation between populations ( $F_{ST}$ ) and subspecies ( $F_{CT}$ ) for populations in which we sampled 8 or more alleles.  $F_{CT}$  is 0 within our dataset, and we found similar levels of  $F_{ST}$  among populations within each subspecies (0.22) *is this an average? this comes from libsequence?* and among all populations (0.23), to those reported in genome-wide estimates from pre-

vious studies (41) (1). *the table caption says just sequence data, but it has hopscotch genotypes too*  
 Although we found large variation in Hopscotch allele frequency among our popula-

Table 1: Pairwise  $F_{CT}$  values from sequence data

Comparison	Seq. Region 2	Seq. Region 1	Hopscotch
EjuA & EJuB	0	0	0
EjuA & MSA	0.328	0.326	0.186
EjuA & SLO	0.258	0.416	0.28
EjuB & MSA	0.365	0.397	0.188
EjuB & SLO	0.29	0.512	0.28
MSA & SLO	0	0.007	0.016

tions, BayEnv analysis did not indicate a correlation between the Hopscotch insertion and environmental variables (all Bayes Factors  $< 1; 3$ ).

## Sequencing

To investigate patterns of sequence diversity and linkage disequilibrium (LD) in the *tb1* region, we sequenced two small ( $<1\text{kb}$ ) regions upstream of the *tb1* ORF in four populations. After alignment and singleton checking we recovered 40 and 48 segregating sites for the 50kb upstream region and the 5' UTR region, respectively. For region 1, Ejutla A has the highest values of haplotype diversity,  $\theta_W$ , and  $\theta_\pi$ , while Ejutla B and La Mesa have comparable values of these summary statistics, and San Lorenzo has much lower values. Additionally, Tajima's D is strongly negative in the two Ejutla populations and La Mesa, but is more positive in San Lorenzo (2). *can drop theta W from table and text. we show pi and D, which is sufficient. fix caption in table. also add Hopscotch allele frequencies to table or list somewhere – i think it's useful for comparison of seq stats*

Table 2: Add caption

Population	# Haplotypes	Hap. Diversity	$\hat{\theta}_W$	$\hat{\theta}_\pi$	Tajima's D
<i>Seq. region 2 (50kb upstream)</i>					
EJUA	8	0.89394	0.01548	0.01763	0.6231
EJUB	8	0.89394	0.01493	0.01591	0.29504
MSA	3	0.68182	0.01111	0.01055	-0.22212
SLO	4	0.74242	0.01167	0.01413	0.93185
<i>Seq. region 1(5' UTR)</i>					
EJUA	8	0.85897	0.00874	0.00527	-1.64955
EJUB	5	0.70909	0.00663	0.00378	-1.83123
MSA	6	0.68182	0.00646	0.00373	-1.75506
SLO	3	0.31818	0.00176	0.00137	-0.72873

For region 2, haplotype diversity,  $\theta_W$ , and  $\theta_\pi$ , are similar for Ejutla A and Ejutla B, while La Mesa and San Lorenzo have slightly lower values for these statistics (2). Tajima's D is positive in all populations except San Lorenzo, indicating an excess of low frequency variants in this population (2). Pairwise values of  $F_{ST}$  within population pairs Ejutla A/Ejutla B and San Lorenzo/La Mesa are 0 for both sequenced regions as well as for the Hopscotch, while they are high for other population pairs (1). Neighbor joining trees of our sequence data and data from the teosinte inbred lines (TILs; data from Maize HapMapV2, (5)) do not reveal any clear clustering pattern with respect to population or Hopscotch genotype (??); individuals within our sample that have the Hopscotch insertion do not group with the teosinte inbred lines or the lines of domesticated maize that have the Hopscotch insertion.

## Evidence of introgression

The teosinte populations *which?* with the highest frequency of the Hopscotch insertion in this study were sympatric with cultivated maize. Our initial hypothesis was that the high frequency of the Hopscotch element in these populations could be attributed to introgression from maize into teosinte. To investigate this possibility we examined overall patterns of linkage disequilibrium across chromosome one, and specifically in the *tb1* region. If the Hopscotch is found in these populations due to recent introgression we would expect to find large blocks of linked markers near this element. We find no evidence of elevated linkage disequilibrium between the Hopscotch and SNPs surrounding the *tb1* region in our resequenced populations (2), and  $r^2$  in the *tb1* region does not differ significantly between populations with (average  $r^2$  of 0.085) and without the Hopscotch genotype (average  $r^2 = 0.082$ ). In fact, average  $r^2$  is lower in the *tb1* region ( $r^2 = 0.056$ ) than across the rest of chromosome 1 ( $r^2 = 0.083$ ) (3).

*table is too wide, need to round numbers, and column headers are messed up.*

Table 3:  $r^2$  values between SNPs in the *tb1* region (positions 264,596,664-265,891,456 on chromosome 1 of the maize AGPv2 genome) and the rest of chromosome 1, within the 5' UTR (Sequenced region 1), and within the 66,169 bp upstream region (Sequenced region 2).

2[2]*Population	2[2]*Chromosome 1	2[2]*tb1 region	2[2]*Seq. region 1	2[2]*Seq. region 1
Ejutla A	0.095426101	0.050304	0.747295	0.214933
Ejutla B	0.068681837	0.051295	0.660354	0.186395
La Mesa	0.069500533	0.053306	0.914286	0.766234
San Lorenzo	0.100536784	0.067251	0.912281	0.636364

The lack of clustering of Hopscotch genotypes in our NJ tree as well as the lack of LD around *tb1* does not support the hypothesis that the Hopscotch insertion in these populations of *parviglumis* is the result of recent introgression. However, to further explore this hypothesis we performed a STRUCTURE analysis using Illumina MaizeSNP50 data from four of our *parviglumis* populations (EjuA, EjuB, MSA, and SLO) and the maize 282 diversity panel (8; ). The linkage model implemented in STRUCTURE can be used to identify ancestry of blocks of linked variants, which would arise as a result of recent admixture between populations. If the Hopscotch insertion is present in populations of *parviglumis* as a result of recent admixture with domesticated maize, we would expect the insertion and linked variants in surrounding sites to be assigned to the "maize" cluster in our STRUCTURE runs, not the "teosinte" cluster. In all runs, assignment to maize in the *tb1* region across all four *parviglumis* populations is low (average 0.017) *is this really 0.017 or 0.17?* and much below the chromosome-wide average (0.20; 3).

*please put figures in the text rather than at the end.*

## Phenotyping

### Phenotyping

To assess the contribution of *tb1* to phenotypic variation in tillering in a natural population, we grew plants from seed sampled from the San Lorenzo population of *parviglumis*, which had a high mean frequency (*X*) of the Hopscotch insertion from our initial genotyping. We measured tillering index (TI), the ratio of the sum of tiller lengths to plant height, for 216 plants from 23 sampling locations within the San Lorenzo population, and genotyped plants for the Hopscotch insertion. *the 23 sampling locales can go in methods and scratch from here* . We found the Hopscotch segregating at

a frequency of 0.65 with no significant deviations from expected frequencies under Hardy-Weinberg equilibrium. After performing a repeated measures ANOVA between our transformed tillering index data and Hopscotch genotype we find a weak positive correlation between presence of the Hopscotch and tillering index on day 40 ( $p=0.0848$ ), but no correlation between tillering index and genotype on any other day (4). Additionally we find no significant correlation between tiller number and Hopscotch genotype, or culm diameter and Hopscotch genotype in phenotyping 1.

*shouldn't we expect a negative correlation between Hop and TI on day 40? need to have an A and B in the figure and explain one is for pheno1 and one is for pheno2. please explain whiskers and dots on figure too.*

*lots of white space in fig 4 and fig. s1 too.* We performed a second grow-out of teosinte to assess whether lighting conditions or sample size may have affected our ability to detect and effect of *tb1*. For the second grow-out we measured tillering index every five days through day 50 for 302 plants. We found the Hopscotch allele segregating at a frequency of 0.69, *does this violate HWE? didn't we choose numbers of each genotype here, so that HWE isn't appropriate? if so, probably should drop genotype frequency data here* with a 0.6 frequency of Hopscotch homozygotes, and a 0.2 frequency of both heterozygotes and homozygotes for the teosinte allele. We found similar patterns, with a weak positive correlation between tillering index and Hopscotch genotype at day 40 ( $p=0.0611$ ), with no significant correlation on any day. Similarly, relationships between Hopscotch genotype and tiller number, and hopscotch genotype and culm diameter are not significant.

## Discussion

Adaptation occurs either due to selection on standing variation or on *de novo* mutations. Adaptation as a result of selection on standing variation has been well-described in a number of systems, for example, selection for lactose tolerance in

humans (40; 49); variation at the *Eda* locus in three-spined stickleback (31; 7); and pupal diapause in the Apple Maggot fly (19). Although the role of standing variation with respect to adaptation has been described in many systems, its importance to domestication is not as well studied.

In maize, alleles at important domestication loci (*RAMOSA1*, (? ); *barren stalk1*, (22); and *grassy tillers1*, (53)) have been shown to have been selected from standing variation, suggesting that diversity already present in teosinte may have played an important role in the domestication of maize. The *teosinte branched1* gene has long been a central focus of research concerning maize domestication, and, while previous studies have suggested that differences in plant architecture between domesticated maize and teosinte are a result of selection on standing variation, little is known about variation at this locus in teosinte (6; 46). Studer et al. (46) genotyped 90 accessions of teosinte (inbred and outbred), providing the first evidence that the Hopscotch insertion is segregating in teosinte (46).

Given that the Hopscotch insertion has been estimated to predate the domestication of maize, it is not surprising that it can be found segregating in populations of teosinte. However, in sampling numerous individuals from many teosinte populations our study provides greater insight into the distribution and prevalence of the Hopscotch in teosinte. While our findings are consistent with a previous study by Studer et al. (46) in that we identified the Hopscotch allele segregating in teosinte, we find it at higher frequency than previously suggested (46). Many of our populations with high frequency of the Hopscotch allele fall in the Jalisco cluster identified by (author?) (Fukunaga), possibly suggesting a different history of the *tb1* locus than in the Balsas region where maize was domesticated [cite matsuoka](#) . While gene flow from crops into their wild relatives is well-known, ((17; 55; 48; 1; 25; 54; 50; 2)), [do all these show evidence of introgression AT domestication loci, or just introgression in general?](#) our results are

more consistent with Hufford et al. (28) who found resistance to introgression from maize into teosinte (28). Furthermore, Hufford et al. (28) showed that domestication loci, such as *tb1*, are particularly resistant to introgression in both directions of gene flow (i.e., maize to teosinte and teosinte to maize) (28).

We find no evidence of recent introgression in our analyses. Clustering patterns in our NJ trees do not reflect a pattern expected if maize alleles at the *tb1* locus had introgressed into populations of teosinte. Moreover, analysis of linkage in the *tb1* region does not reveal patterns of high LD relative to the rest of chromosome 1, and assignment to maize in this region in our STRUCTURE analysis is lower than the average across chromosome 1 (3, 4). Together, these data point to an explanation other than recent introgression for the high observed frequency of Hopscotch in some of our *parviglumis* populations.

Table 4: Assignments to maize and teosinte in the *tb1* and chromosome 1 regions from STRUCTURE

Population	<i>tb1</i> region		Chr 1	
	Maize assignment	Teosinte assignment	Maize assignment	Teosinte assignment
Ejutla A	0.02158681	0.9784132	0.2026814	0.7973186
Ejutla B	0.01888194	0.9811181	0.1872131	0.8127869
La Mesa	0.9881333	0.0118675	0.8068998	0.1931017
San Lorenzo	0.01551389	0.9844861	0.2048252	0.7951748

Although recent introgression seems unlikely, we cannot rule out ancient introgression as an explanation for the presence of the Hopscotch in these populations. If the Hopscotch allele was introgressed in the distant past, they could have been sufficient recombination to break up any initial LD, leading to observations similar to those obtained here. We find this scenario less plausible, however, as there is no

reason why gene flow should have been high in the past but absent in present-day sympatric populations. In fact, early generation maize-teosinte hybrids are easy to find in these populations today (MB Hufford, pers. observation), and genetic data support ongoing gene flow between domesticated maize and both *Zea mays* ssp. *mexicana* and *Zea mays* ssp. *parviglumis* in a number of sympatric populations (28; 16?).

Other explanation for differential frequencies of the Hopscotch among teosinte populations include both drift and natural selection. Previous studies using both SSRs and genome-wide SNP data have found evidence for a population bottleneck in the San Lorenzo population (26; ), and the lower levels of sequence diversity in the 5' UTR region and the more positive values of Tajima's D we present here are consistent with these findings. *deviations from HWE may be consistent too if we see excess of homozygotes. do we?* . This bottleneck, however, does not explain differences in Hopscotch allele frequency among populations, and the available information on diversity and population structure among these populations (26; ) is not suggestive of colonization or other demographic events that might predict a high frequency of the allele in multiple populations. *here we need a few sentences on selection. the 5' UTR has much more negative D than the upstream. do we know the Hop genotype for sequenced lines? can we separate the sequences into hop/no hop and look for differences? it wasn't until we did this that gt1 stuff really popped out.*

The phenotypic effects of the Hopscotch insertion in domesticated maize have been well documented (6; 46), *did clark do phenotyping?* and Weber et al. (52) have described its effects in partially inbred lines of teosinte (52) *i don't think these were inbred. please doublecheck.* . Our study is the first to explicitly examine the phenotypic effects of the Hopscotch insertion in individuals sampled from a natural population of teosinte. *isn't this what weber did?? for 70+ populations!?* However, we found no significant effect of the Hopscotch on tillering index or tiller number in our phenotyping experiments, and

the effect of the Hopscotch insertion in teosinte is discordant with that of maize. The lack of correlation between Hopscotch genotype and tillering index or tiller number is surprising given its effects in maize. It is certainly possible that even though previous data demonstrate an effect of the Hopscotch on tillering in maize (46), that the effect of the Hopscotch in teosinte is more complicated and may be more difficult to observe. Moreover, *tb1* is a single gene in a complex pathway that affects branching and tillering traits, and perhaps in combination with alleles at other loci the phenotypic effects of the Hopscotch on tillering may not be consistent. *this section still needs work. i think we have to do more here. weber shows an association between SNPs in tb1 and branch length. we need to discuss that!*

*MBH todo* Variation at *tb1* has also been shown to contribute to phenotypes other than tillering (6), and a recent study by Studer and Doebley (45) examined the possibility of an allelic series at the *tb1* locus in teosinte. Studer and Doebley (45) introgressed 9 separate teosinte segments (one from *Zea diploperennis*, and four from both *Zea mays* ssp. *mexicana* and *Zea mays* ssp. *parviglumis*) spanning the *tb1* locus into an isogenic maize background and investigated their effects on previously associated phenotypes. They found that plants with teosinte chromosomal segments had greater tillering than their maize isogenic lines, and that different chromosomal segments of *tb1* confer different amounts of tillering, suggesting that there are multiple genetic factors in this region that affect tillering. However, in addition to elucidating variance in tillering among *tb1* teosinte segments, Studer and Doebley (45) found significant variance among W22 control lines, suggesting that there are other genetic factors aside from alleles at the *tb1* locus that affect tillering in maize. Doebley and Stec (11, 12) first attempted to map QTL controlling many of the phenotypic differences between domesticated maize and teosinte, and demonstrated the existence of numerous QTL that contribute to the differences in branching architecture between

the two. Many of these loci (*grassy tillers*, *gt1*; *tassel-replaces-upper-ears1*, *tru1*; *terminal ear1*, *ter1*) have been shown to interact with *tb1* (53; 33? ), *yup*, *cite some PAPERS* and both *tru1* and *ter1* have been shown to affect the same phenotypic traits as *tb1* (13). *tassel-replaces-upper-ears1* (*tru1*), for example, has been shown to act either epistatically or downstream of *tb1*, affecting both branching architecture (decreased apical dominance) and tassel phenotypes (shortened tassel and shank length and reduced tassel number) (33). It seems plausible that variation in some of these other loci could have affected tillering in our greenhouse population, and contributed to the lack of correlation we see between Hopscotch genotype and tillering.

In summary, our findings demonstrate that the Hopscotch allele is more widespread in populations of *parviglumis* and *mexicana* than previously thought. Analysis of linkage using SNPs from across chromosome 1 does not suggest that the Hopscotch allele is present in these populations due to recent introgression; however, it seems unlikely that it would have drifted to high frequency in multiple populations and there may be another explanation for the high frequency we observe in some of our populations. The Hopscotch does not appear to have a strong effect reducing tillering in teosinte as it does in maize, and other loci involved in branching architecture may play also play roles in the regulation of tillering in teosinte. Finally, although we see no clear evidence of recent strong selection, the high frequency of the Hopscotch insertion in a number of populations continues to suggest to us that it plays an ecological role in teosinte. In the future, additional experiments will be needed to examine expression levels of *tb1* and additional loci involved in branching architecture (e.g. *gt1*, *tru1*, and *ter1*) in conjunction with a more exhaustive phenotyping and genotyping assay. *why not Phyb and phya?*

*please check format of supp figs and tables; some are running off the page. check fig/table references, bibliography, etc. what does "rotation" mean in supp. table 3? it isn't mentioned in methods. please check that all the*

*tables and figs (including supplement) are referenced in the text.*

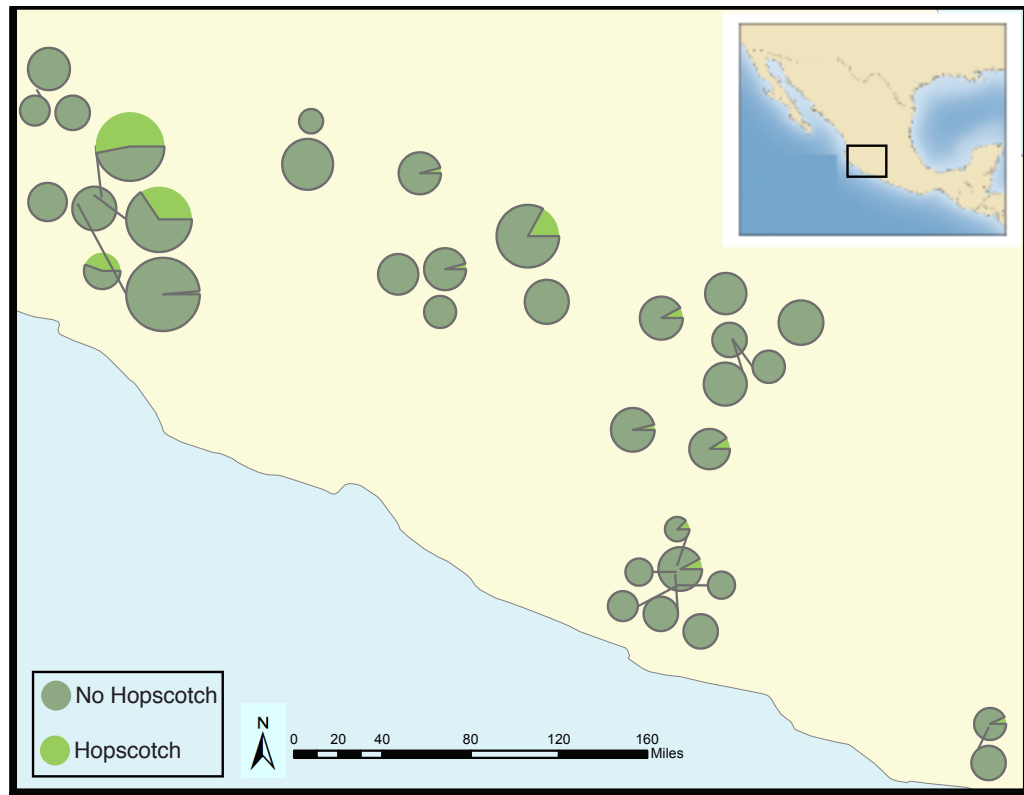

Figure 1: Map showing the frequency of the Hopscotch allele in populations of *Zea mays* ssp. *parviglumis* where we sampled more than 6 individuals. Size of circles reflects number of alleles sampled.

Figure 2: Linkage disequilibrium for SNPs in Mb 261-268 on chromosome 1. The yellow rectangle indicates the location of the Hopscotch insertion and the green represents the *tb1* ORF. A) Ejutla A; B) Ejutla B; C) La Mesa; D). San Lorenzo

Figure 3: STRUCTURE assignment to maize across a section of chromosome 1. The dotted lines mark the beginning of the sequenced region 50kb upstream (Sequenced region 2) and the end of the *tb1* ORF.

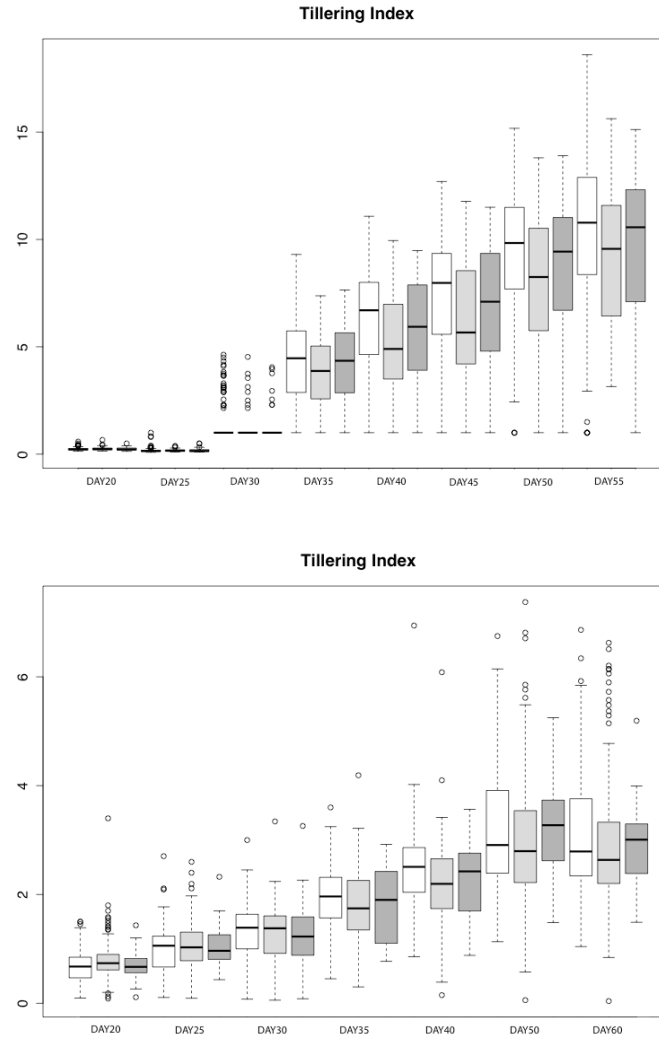

Figure 4: Box-plot showing tillering index in our greenhouse population from day 20-60. White indicates individuals homozygous for the Hopscotch, light grey represents heterozygotes, and dark grey represents homozygotes for the teosinte (No Hopscotch) allele. Within boxes, dark black lines represent the median, and the edges of the boxes are the first and third quartiles.
